SESSION TYPE: Webinar|Platform

ABSTRACT BODY:

Background: Delirium is a well-described complication of critical illness. Studies in the Pediatric Intensive Care Unit demonstrate prevalence rates of up to 20%. Infants in the highly medicalized NICU environment are likely at risk, yet there are only a handful of reports of NICU delirium. There have been no previous screening studies to quantify delirium prevalence in the neonatal population.

Objective: The objectives of our study were to assess feasibility of delirium screening, establish prevalence of delirium, and analyze risk factors for a positive delirium screen.

Design/Methods: All term or term-corrected ($\geq 37+0$ weeks) infants admitted to a level IV NICU were screened for delirium using the Cornell Assessment for Pediatric Delirium (CAPD) over eight study days; CAPD score ≥ 9 was positive for delirium. Additional information collected included: gestational age at birth; recent exposure to opiates, benzodiazepines or steroids; respiratory support; recent surgery; and known neurological disorder potentially altering level of arousal/activity.

Results: Of 151 eligible infants, 147 (97.3%) were screened for delirium. Overall prevalence of a positive delirium screen was 33 (22.4%). Among infants without co-existing neurological disorder, prevalence was 13.3%. After controlling for neurological disorder, prevalence of delirium was significantly higher for those infants recently exposed to opiates, benzodiazepines or steroids, compared to those who were not (53.3% vs 6.9%, $p < 0.0001$). Adjusted odds ratio for positive delirium screen was 7.25 ($p = 0.0003$) (Table).

Intubation/tracheostomy status was also associated with a positive delirium screen (15.2% vs 1.8%, $p = 0.0002$). There was no evidence of association between delirium and babies born term/premature or recent surgery (Table).

For infants with a co-existing neurological disorder, delirium was not associated with use of opioids/benzodiazepines/steroids (66.7% vs 57.1%, $p = 0.70$). For infants without a co-existing condition, delirium was associated with use of opioids/benzodiazepines /steroids (53.3% vs 6.9%, $p < 0.0001$), (Figure).

Conclusion(s): Screening for delirium is feasible in term-born and term-corrected age infants admitted to the NICU. More than 20% of such infants screen positive. Prevalence of positive delirium screen remains high when infants with underlying neurologic disorders are excluded. Respiratory support and medications known to be deliriogenic in older subjects were associated with a positive screen.

	Positive Delirium Screen	Negative Delirium Screen	Adjusted Odds Ratio [95% CI]*	p-value
All eligible babies (n=147)	33 (22.4%)	114 (77.6%)

SESSION TYPE: Webinar|Platform

ABSTRACT BODY:

Background: For very preterm infants, birth to term equivalent age is a critical period for brain growth and development. Differentiating lean from fat mass describes the quality of physical growth during this period and may index brain growth and maturation. But, little is known about the relationships between body composition and regional brain growth or white matter maturation.

Objective: To assess associations of body size and composition with 1) total brain volume, 2) volumes of brain regions known to be sensitive to nutritional perturbations (hippocampus, cerebellum), and 3) white matter microstructure at term equivalent age among very preterm infants. We hypothesized greater lean mass—but not fat—would be associated with larger hippocampus and cerebellum volumes, and higher fractional anisotropy (FA) of early myelinating white matter tracts.

Design/Methods: Prospective observational study of 85 infants born <33 wks' gestation. At median postmenstrual age 39.3 wks, infants underwent air displacement plethysmography to measure body composition (from which we calculated Z-scores of lean and fat mass, weight, length, and body mass index) and brain magnetic resonance imaging (MRI). From MRI we assessed 1) total brain volume; 2) regional volumes from automated segmentation (MANTiS); 3) white matter microstructure using diffusion tensor imaging to calculate FA of 15 white matter tracts (listed in Table 2). We estimated associations of body size and composition with brain volumes and FA, using generalized estimating equations to adjust for covariates and account for multiple births.

Results: Infants were 57% male, median gestational age 29.1 wks (range 23.4, 32.9). Body size and lean mass were positively associated with volumes of most brain regions including the cerebellum, and with total brain size; whereas fat was not (Table 1). Body size and lean mass—but not fat—were also positively associated with FA in multiple white matter tracts (Table 2). Specifically, one unit increase in lean mass Z-score was associated with greater FA in: left cingulum 0.3%; left corticospinal tract 0.5%; and right posterior limb of the internal capsule 0.3%.

Conclusion(s): Greater lean mass—but not fat—at term equivalent age was associated with larger total brain and cerebellar volumes and alterations in white matter microstructure. Lean mass accrual may index brain growth and white matter development among preterm infants. Nutritional factors that promote lean mass accretion may also promote brain growth and maturation.

Table 1. Associations of body size and composition with total and regional brain volumes at term equivalent age among 85 very preterm infants.

SESSION TITLE: Neonatal General: Brain |Neonatal General: Brain

SESSION TYPE: Webinar|Platform

ABSTRACT BODY:

Background: Extremely low gestational age (ELGA, < 29 wks GA) newborns are at high risk to develop germinal matrix intraventricular hemorrhage (GM-IVH) within the first 3 days after birth. The GM-IVH results in poor neurodevelopmental outcomes. This risk relates to the immaturity of the vascular bed within the germinal matrix, which is particularly vulnerable to dysregulation of cerebral blood flow (CBF).

Objective: Therefore, optimal therapeutic strategies that maintain cerebrovascular stability is needed in ELGA; however, we lack a reliable continuous monitoring of CBF. To address this unmet need, we developed a diffuse correlation spectroscopy (DCS, 785nm) system and flexible optical sensors (Figure 1) to continuously monitor CBF in ELGA infants during their first three postnatal days.

Design/Methods: To date, we have enrolled 9 newborns (3 ELGA infants). We monitored them with DCS for 2-6 hours a day during the first few days after birth. We also co-recorded electrocardiogram, pulse oximetry, and when available invasive blood pressure, transcutaneous pCO₂, and regional cerebral oximetry. The presence of IVH was assessed from the head ultrasound on days 1, 3, 7, and 30 of life. We computed cross-correlation between CBF_i responses to fluctuation in mean arterial blood pressure (MAP) to quantify the degree of dysfunction in cerebral autoregulation (e.g., pressure passive events). A sliding window of 2.5 minutes was used to find a peak correlation (R) within 20 seconds of lag, and response time (Tr) was identified at the time of the peak correlation. A bootstrapped null distribution was used to test the significance of the correlation (Pr).

Results: This report summarizes the results of a pair of 23 wks GA twins. When baby A was compared to baby B, A had significantly higher probability of pressure passive events than baby B (p=0.046, Chi-square test, Table 1). Also, significantly shorter response time and unstable MAP had been detected in baby A than B, which suggests more reactive yet disruptive cerebral autoregulation. Although both babies developed Grade II IVH, while baby A had an ultrasound diagnosis of IVH at day 2 of life, IVH was not detected until day 7 of life in baby B.

Conclusion(s): We assessed cerebral autoregulation in ELGA infants using continuous CBF monitoring via DCS and signal cross-correlation. This can help clinicians to make informed decisions and foster the development of new interventions that can stabilize CBF and prevent IVH in ELGA infants.

Indices of pressure passive events in twin ELGA infants A and B

Indices ELGA	A	B	P-value

ABSTRACT BODY:

Background: Exposure to antibiotics, in the absence of infection, results in abnormal brain function in animals which is linked to changes in gut microbes. The hippocampus, a brain region important for recognition learning and memory, is a target of microbe-mediated effects on the brain. Studies in germ-free mice have shown that there is an early-life sensitive period for gut microbe effects on neurodevelopment.

Objective: To test the hypothesis that neonatal exposure to antibiotics affects recognition memory responses in human infants.

Design/Methods: Auditory recognition memory (mother-stranger voice paradigm) was assessed at 1 month of age in 15 infants born at term and exposed to antibiotics, but with negative cultures, and a subset of 57 term infants in the Mothers and Infants Linked for Health Growth (MILk) Study not exposed to antibiotics, using event-related potentials (ERPs).

Linear regression analysis, with adjustment for covariates such as birth mode, gestational age at birth, and sex, was employed to compare groups with respect to ERP features that represent early stimulus processing and discrimination (P2 amplitudes) between mother and stranger voices.

Results: Infants exposed to antibiotics exhibited smaller overall mean P2 amplitudes for both mother and stranger voice conditions ($p = 0.001$), with the greatest reduction (more negative beta coefficients in bold) observed in response to mother's voice in right and left frontal and right central scalp regions (Table). In addition, infants exposed to antibiotics showed larger P2 amplitudes to stranger's as compared to mother's voice, a reversal of the typical response exhibited by infants not treated with antibiotics (Figure, compare mother to stranger response change within each infant treatment group). In an exploratory analysis within the group of infants exposed to antibiotics, abnormal ERP responses did not correlate with increased inflammatory cytokine concentrations (tumor necrosis factor alpha, interleukin-1-beta, interleukin-6, interleukin-8, and interferon gamma).

Conclusion(s): Otherwise healthy infants born at term gestation and exposed to antibiotics soon after birth demonstrated altered auditory processing and discrimination responses at one month of age, supporting the presence of a microbiota-gut-brain axis in humans during very early life.

Association of antibiotic exposure with mean P2 amplitude by lead grouping

SESSION TITLE: Neonatal General: Brain |Neonatal General: Brain

SESSION TYPE: Webinar|Platform

ABSTRACT BODY:

Background: Very preterm infants are at high risk for motor impairments. Qualitative brain imaging is commonly used to assess risk, however accurate prediction remains elusive especially in infants without severe brain injury.

Objective: To determine whether automatically-quantified brain volume measurements on term MRI are independent predictors of motor outcomes in preterm infants, above and beyond known clinical risk factors and semi-quantitative structural MRI readings.

Design/Methods: Prospective cohort of preterm infants born ≤ 31 weeks gestation from four level III NICUs in Columbus, Ohio of 94 infants without severe injury or motion artifacts using 3T MRI scanner (1mm³ resolution) at term-equivalent age. Motor testing was performed using the Bayley Scales of Infant and Toddler Development, Third Edition at two years corrected age. Automated volumetric analysis was performed using the Developing Human Connectome Project pipeline. Structural MRI scans were reviewed by a three pediatric neuroradiologists and global brain abnormality score per Kidokoro et al. (2013) was assigned by first author. Biometric measurements were done by first author and demonstrated high intra-rater reliability (n=20, intra-class coefficients 0.82 – 0.99). We used multivariable regression to evaluate the independent value of relative brain volumes (adjusted for total tissue volume) above clinical predictors and Kidokoro score (Table 1) for predicting motor outcomes.

Results: 75 of the 94 infants (80%) returned for developmental testing (Table 2). Several regional volumes were significantly associated with motor outcomes in univariate analyses (Table 3). For motor impairment (Bayley Motor <80), the area under the receiver operating characteristic curve (AUC) for clinical predictors and Kidokoro score was 0.91; with the addition of brain volumes, it improved to 0.96 (Table 4). Similarly, addition of brain volumes to clinical predictors and Kidokoro score improved the adjusted R² value for the Bayley Motor score from 0.33 to 0.55, with several regional volumes showing significance or trend towards significance in predicting motor scores (Table 4).

Conclusion(s): In our regional cohort, objectively-quantified regional brain volumes at term independently improved the accuracy of predicting motor outcomes beyond existing clinical and structural imaging predictors in very preterm infants without severe brain injury. External validation in a large sample of infants is needed.

Table 1. Baseline characteristics of clinical predictors of motor development and the Kidokoro global brain abnormality score at term-equivalent age in very preterm infants.

Clinical Variable	Very Preterm Infants with Follow-up (N=75)
Sex, male n (%)	31 (41.3)
Birth weight (grams), median (range)	1075 (445 – 2340)
Gestational age (weeks), median (range)	28.6 (23.7 – 31.9)
Disadvantaged socioeconomic status, n (%)	40 (53.3)
Severe bronchopulmonary dysplasia, n (%)	22 (27.5)
Severe retinopathy of prematurity, n (%)	8 (10)
Intra-uterine growth restriction	7 (8.8)
White matter or cerebellar injury on head ultrasound after 35-weeks corrected age	12 (15)
Kidokoro score, n (%)	
No brain abnormality	48 (68.7)
Mild brain abnormality	20 (26.7)
Moderate brain abnormality	9 (12.0)
Severe brain abnormality	2 (2.7)

SESSION TYPE: Webinar|Platform

ABSTRACT BODY:

Background: Very preterm infants are at risk for cognitive impairment. Standard imaging tools, including head ultrasound and qualitative brain MRI, do not reliably predict cognitive outcomes. Regional brain volumes at term have shown conflicting prognostic value and have not been adequately compared with existing predictors or cognitive outcomes beyond 2 years corrected age.

Objective: To determine whether automated brain volume measurements on term MRI improves ability to predict cognitive outcomes at 3 years corrected age, independent of clinical predictors and structural MRI.

Design/Methods: Prospective cohort of 110 very preterm infants (31 weeks gestation) were enrolled from 4 level III NICUs in Columbus, Ohio. Brain MRI was done at term-equivalent age using 3T scanner (1 mm³ resolution). General conceptual score (GCA) on the Differential Ability Scales (DAS)-II was our primary outcome. Automated volumetric analysis was successful in 94 subjects (subjects excluded for severe brain injury or motion artifacts) using the Developing Human Connectome Project pipeline to yield more than 200 regional brain volumes. Structural MRI scans were read by 3 pediatric neuroradiologists and biometric measurements were obtained by the first author with high intra-rater reliability (n=20; ICC 0.82 – 0.99) to yield a global brain abnormality score per Kidokoro et al. (2013). We used multivariable regression to assess independent value of relative brain volumes (divided by total tissue volume) over and above known clinical predictors and Kidokoro score for predicting cognitive outcomes (Table 1).

Results: Of the 94 very preterm infants with successful imaging, 80 (81%) returned for DAS-II testing at 3 years corrected age (Table 2). In univariate analyses, several relative regional volumes were significantly correlated with the DAS-GCA score (Table 3). Some volumes remained significant in multivariable analysis, independent of Kidokoro score and injury on head ultrasound. Addition of volumes to prediction model improved performance of prediction of cognitive impairment (Table 4).

Conclusion(s): In our regional cohort, objectively-quantified regional brain volumes improved performance of prediction model for cognitive impairment. This data suggests that there may be a role for brain volumes in prediction of cognitive outcomes of preterm infants, especially those without severe brain injury.

Table 1. Baseline characteristics of clinical predictors of cognitive outcomes and the Kiddo global brain abnormality score in very preterm infants.

Clinical Variable	Very Preterm Infants with Follow-up (N=80)
Sex, male n (%)	32 (40)
Birth weight (grams), median (range)	1075 (465 - 1900)
Gestational age (weeks), median (range)	29.1 (23 - 31.9)
Disadvantaged socioeconomic status, n (%)	46 (57.5)
Severe bronchopulmonary dysplasia, n (%)	22 (27.5)
Severe retinopathy of prematurity, n (%)	8 (10)
Intra-uterine growth restriction, n (%)	7 (8.8)
Injury on head ultrasound after 33 weeks corrected age, n (%)	12 (15)
Kiddo score, n (%)	47 (58.8)
No brain abnormality	21 (26.3)
Mild brain abnormality	9 (11.3)
Moderate brain abnormality	9 (11.3)
Severe brain abnormality	3 (3.8)

Table 2. Cognitive testing with the Differential Ability Scales, second edition (DAS-II) at 3 years corrected age results.

DAS-II Outcome	Very Preterm Infants with Follow-up (N=80)
General conceptual ability Median (Range)	90 (36 - 120)
Nonverbal subtest Median (Range)	92 (39 - 132)
Verbal subtest Median (Range)	89 (25 - 132)
Cognitive impairment N (%)	18 (22.5)

Table 3. Regional relative brain volumes significantly associated with cognitive outcomes in univariate analysis.

Outcome measure	Relative regional brain volume	P value
DAS-GCA	Cerebral Spinal Fluid (CSF)	0.005
	Thalamus low intensity in T2	0.012
	Hippocampus	0.013
	Hippocampi and amygdala	0.021

ABSTRACT BODY:

Background: Chronic lung disease (CLD) is a significant risk factor for developmental delays in children born preterm. Most studies assessing preterm infants with CLD have performed neurodevelopmental exams at or after 12 months of age, with no known studies in patients prior to discharge from the NICU.

Objective: To determine whether CLD severity in preterm infants is associated with atypical neurobehavior and cry acoustics prior to hospital discharge.

Design/Methods: Infants born <30 weeks post-menstrual age (PMA) were enrolled in the multicenter Neonatal Neurobehavior and Outcomes in Very Preterm Infants (NOVI) Study. The NICU Network Neurobehavioral Scale (NNNS) was administered at discharge, and risk profiles and summary scores calculated. Maximum likelihood factor analysis was performed on cry acoustics. Generalized estimating equations examined the associations of CLD severity with NNNS scores and cry factors adjusting for site, maternal and neonatal complications, and PMA at birth and NNNS.

Results: Of 709 enrolled NOVI infants, 676 had complete medical and NNNS data; 177 (26.2%) had moderate/severe (mod/sev) CLD, and 163 (24.1%) had mild CLD. Maternal and infant characteristics differed by CLD severity (Table 1). Factor analysis of cry data (n=418) revealed two factors that explained the greatest proportion of variation: frequency/energy (loudness) and hyperphonation (high pitch). Cry factors were not associated with CLD. Infants with mod/sev CLD were 3 times more likely to have an overall atypical NNNS risk profile when compared to infants without CLD (OR=3.09; 95% CI:1.02, 9.37). Comparisons for individual NNNS summaries indicated that mod/sev CLD was associated with lower NNNS attention scores and increased lethargy. Mod/sev CLD was also associated with lower quality of movement compared to mild CLD, and with lower arousal compared to no CLD (Table 2).

Conclusion(s): Severity of CLD in preterm newborns at the time of hospital discharge was associated with specific neurobehavioral patterns. Identification of targeted neurobehavioral problems by administering the NNNS in these at-risk newborns prior to NICU discharge may lead to earlier initiation of specific therapeutic interventions with potential to improve long-term outcomes.

Table 2. CVD severity by NIMS lumbar scores

	No CVD (n)		Mild CVD		Moderate/Severe CVD		Multiple Comparison P ^a	
	Mean	SD	Mean	SD	Mean	SD	(L1/L2)	(L3/L4)
Severity	3.20	0.22	3.46	0.24	4.70	0.28	0.19	0.06
Quality of movement	4.97	0.08	4.82	0.08	4.45	0.07	0.05	0.44
Balance	7.70	0.09	7.62	0.09	7.31	0.08	0.40	0.02
Latency	3.11	0.14	3.07	0.23	3.00	0.30	0.81	0.01

^aAdjusted for age, BMI, all 6 clinical symptoms, extent of disability, functional status, gait speed, standing balance, and brain injury.
